

The Bandwidth Lapse and the Factor of Two: The Weak-Field Einstein Metric in Event Density

Allen Proxmire

June 2026

Abstract

Event Density's published gravity arc recovers Newton's law and a relativistic-MOND sector on a *postulated* acoustic metric (Paper_033), leaving the metric's explicit form — and hence the light-bending coefficient — unspecified. This paper supplies the **explicit emergent metric** and derives the **weak-field gravity** it produces. The spatial metric is the bandwidth metric $g_{ij} \sim b_{ij}^{-1}$ (P04). The new content is the **temporal lapse**: requiring the substrate front (the maximal signal, the null cone) to be null on $g_{ij} \sim b^{-1}$, together with the certified commitment-rate law $\Gamma_{\text{commit}} \sim b_{\text{int}}/\text{reserve}$ — linear in bandwidth (postulate **P-Commitment-Linear**, §2) — forces

$$N^2 \sim b.$$

Hence $g_{00}, g_{rr} \sim (-b)(b^{-1}) = -1$ — the **Schwarzschild relation**, the Einstein branch, not the conformal (Nordström) one. Combining this relation with the inherited Newtonian limit $\nabla^2 b \sim \rho$ (Paper_027) assembles the **weak-field Schwarzschild metric** $g_{00} = -(1 - r_s/r)$, $g_{rr} = (1 - r_s/r)^{-1}$. From it follow the three classical tests: the **factor-of-two light bending** (the optical index is $n_{\text{opt}} \sim b^{-1}$, the *square* of the spatial-only index, so the deflection is exactly twice the Newtonian value; a self-contained eikonal simulation confirms $\alpha \sim r_s/x$ with an Einstein/Newtonian ratio of 2.09 versus 2.000, and zero for the conformal control), **gravitational redshift** ($N \sim b^{1/2}$, a free corollary), and **perihelion precession** (test particles in the derived metric). The leading-order metric coincides with General Relativity's; the paper makes no claim of the full field equation (GR-II), no claim of pure GR (the gravity is khronometric — Einstein-class at weak field), and no claim that G , 1_P , or the commitment-rate linearity are derived rather than inherited or postulated.

1. Introduction

1.1 What this paper does

ED's flat-spacetime gravity arc (Papers 025–031) recovers Newton + the MOND transition acceleration + BTFR; Paper_033 covariantizes it as a scalar-tensor theory on a **postulated**

acoustic metric. The metric's explicit form was left unspecified, and with it the spatial curvature that decides whether light bends by the Newtonian amount or the (twice-larger) Einstein amount. This paper closes that gap in four steps:

1. The explicit emergent **spatial** metric $g_{ij} \sim b^{-1}$ (§3).
2. The **temporal lapse** $N^2 \sim b$, derived from the commitment-rate law and the null condition (§4) — the core new result.
3. The **weak-field metric** assembled from the lapse + the inherited Newtonian profile, yielding the Schwarzschild relation (§5).
4. The **three classical tests**, including the **factor of two** (§5–§6), with a simulation validating the lensing mechanism.

1.2 Why this matters

The factor of two in light bending is the historical discriminator between Newtonian/scalar gravity (which bends light half as much) and Einstein gravity (which bends it twice as much, because space curves as much as time). A substrate theory that recovers Newton but not the factor of two would be sub-Einstein; one that recovers it has reproduced the first genuinely *relativistic* gravitational prediction. This paper shows ED lands on the Einstein value, and locates exactly why: the same bandwidth field sets both the spatial metric and the temporal lapse, so space and time curve together.

1.3 How this fits the arc

- **Paper_027 / 027.5:** Newton's law; $G = c^3 l_P^2 / \hbar$; $l_{ED} = l_P$. (*inherited base*)
- **Paper_033:** scalar-tensor acoustic-metric covariantization (postulated metric; pre-pivot). (*this paper sharpens*)
- **Paper GR-I (this paper):** the explicit bandwidth metric + weak-field Einstein tests.
- **Paper GR-II (companion):** the field-equation form (Lovelock) and the gravitational class (mode count $\rightarrow$ khronometric); Lorentz safety.

This is the first paper of the post-pivot curvature-emergence line: where Paper_033 *posited* a metric and got MOND, this paper *derives* a metric and gets the weak-field Einstein tests.

1.4 Conventions and regime of validity

Conventions. Metric signature $(-, +, +, +)$; static coordinates; $c = 1$ where convenient. The weak-field metric is written in **isotropic gauge**: $ds^2 = -(1 + 2\Phi)dt^2 + (1 - 2\Phi)\delta_{ij}dx^i dx^j$. The Schwarzschild-gauge form used in §5.3 ($g_{rr} = (1 - r_s/r)^{-1}$) is the same metric in a different radial coordinate and agrees with the isotropic form to the weak-field order computed; the relation $g_{00}, g_{rr} \sim -1$ is the gauge-robust content that distinguishes the Einstein branch from the conformal one.

Regime of validity. Every result here is **static**, **weak-field**, **spherically symmetric**, and lives in the **continuum (DCGT) limit** of the substrate (Paper_073). No strong-field, time-dependent, or non-spherical claim is made: the vacuum profile (§5.2) is the Newtonian-order $1/r$, the metric is its leading weak-field completion, and the full nonlinear / strong-field field equation is deferred to GR-II. The factor-of-two simulation (§6) is an imposed-profile validation of the propagation mechanism, not a strong-field solution.

2. Primitive Inputs

Substrate primitives (postulated, Paper_087): P02 (reciprocal adjacency), P04 (four-band bandwidth), P05 (adjacency transport), P11 (commitment irreversibility), P13 (homogeneous tick). Load-bearing as in the Phase-3 analysis.

Kernel dependence: V1 finite-width retarded structure (Paper_089) for the causal/temporal sector; the finite-width bandwidth-limit speed supplies the light cone.

Paper-specific postulate (labeled per QC discipline):

- **P-Commitment-Linear (commitment rate linear in bandwidth):** *The substrate commitment rate $\Gamma_{\text{commit}} \sim b_{\text{int}}/\text{reserve}$ (commitment.md) is linear in the metric-relevant bandwidth, $\Gamma \sim b$, to leading order.* This holds when the P04 commitment-reserve band does not co-scale with the internal band (P04 lists them as distinct bands). With $\Gamma \sim b^\alpha$, the lapse is $N^2 \sim b^{2\alpha-1}$: $\alpha = 1$ gives the Schwarzschild/Einstein relation; $\alpha = 0$ gives the conformal/Nordström one. P-Commitment-Linear selects $\alpha = 1$. It is a substrate-level structural commitment, **not** derived from the four-band law alone, and labeled here for transparency. The exact reserve dynamics that would fix α are deferred to GR-II.

Why linearity is the natural choice (and the alternatives are not). Three considerations select $\alpha = 1$, none of which is a fit to a desired answer. (i) *The rate's own form.* $\Gamma_{\text{commit}} \sim b_{\text{int}}/\text{reserve}$ is the internal bandwidth divided by a reserve budget; treating the reserve as a roughly fixed budget (a *distinct* P04 band) makes Γ rise in direct proportion to the available internal bandwidth — linearity is the leading, unforced reading. (ii) $\alpha = 0$ (conformal/Nordström) *is physically implausible.* It requires the commitment rate to be *independent* of bandwidth — equivalently, the reserve to track the internal band exactly so their ratio is constant — i.e. a front that commits no faster where there is more capacity, contradicting the meaning of bandwidth as commitment capacity. It is also the branch that bends no light at all (conformally-flat metrics are non-lensing, §6.3). (iii) $\alpha \neq 1$ *breaks the null-cone identification.* Any $\alpha \neq 1$ gives $N^2 \sim b^{2\alpha-1} \neq b$, so the front's coordinate speed ($\sim \Gamma \sim b^\alpha$) and the lapse no longer combine, through the null condition (§4), into a single b -controlled cone; the spatial and temporal curvatures cease to be locked to one field, and the Schwarzschild relation $g_{00}g_{rr} \sim -1$ is lost. Linearity is the unique exponent for which one field b controls one consistent causal cone — the structure §6 needs for the factor of two.

Upstream paper dependencies:

- **Paper_087:** position paper (13 primitives).
- **Paper_027 / 027.5:** Newton recovery; $G; 1_{\text{ED}} = 1_{\text{P}}$.
- **Paper_033:** acoustic-metric postulate (sharpened here).
- **Paper_073:** DCGT continuum-limit bridge.
- **Paper_089:** V1 finite-width kernel (cone / lapse-speed).

Empirical / value-layer inputs (inherited, not derived):

- **Newton's constant** $G = c^3 l_P^2 / \hbar$ and $l_{ED} = l_P$ — value-INHERITED (Paper_027/027.5).
- **The source distribution** ρ (matter / event density) — astrophysical input.

No primitive forcing is invoked.

2.5 Load-Bearing Step Audit

Step	Status	Source / justification
13 primitives postulated	P	Paper_087
Newton's law / Poisson $\nabla^2 \Phi = 4\pi G \rho$	I	Paper_027
$G = c^3 l_P^2 / \hbar$, $l_{ED} = l_P$	I	Paper_027/027.5 (M3; value-inherited)
Emergent spatial metric $g_{ij} \sim b^{-1}$	D	§3 — explicit bandwidth realization of the Paper_033 acoustic-metric postulate; symmetric (P02), bulk-positive, degenerates at $b \rightarrow 0$ (horizons)
Front = null cone (maximal signal)	D	§4.1 — bandwidth-limit speed (V_1 / Paper_089) is the substrate's maximal signal speed
Commitment rate $\Gamma \sim b$	P (P-Commitment-Linear)	§2 postulate; selects the Einstein branch ($\alpha = 1$) over conformal ($\alpha = 0$)
Lapse $N^2 \sim b$	D conditional on P-Commitment-Linear	§4.2 — front-null condition with $g \sim b^{-1}$ and $dx/dt = \Gamma \sim b$
Schwarzschild relation $g_{\{00\}} g_{\{rr\}} \sim -1$	D	§5.1 from $N^2 \sim b$, $g_{\{rr\}} \sim b^{-1}$
Vacuum profile $b = 1 - r_s/r$	D conditional on I	§5.2 from inherited Newtonian $\nabla^2 b \sim \rho$ ($\nabla^2 b = 0$ in vacuum)
Weak-field Schwarzschild metric	D	§5.3 (relation + profile)
Optical index $n_{opt} \sim b^{-1}$	D	§6.1 from $g_{\{rr\}} \sim b^{-1}$, $N^2 \sim b$
Factor-of-two light bending	D + simulation	§6.2 — n_{opt} is the square of the spatial index; eikonal sim confirms ratio 2.09 vs 2
Gravitational redshift	D	§5.4 corollary of $N \sim b^{\{1/2\}}$

Step	Status	Source / justification
Perihelion precession	D (test-particle)	§5.4 standard geometry in the derived metric; timelike-worldline identity assumed (preamble 9)
Imposed b -profile in the sim	regime / I	§6 — profile from inherited Newtonian limit, not a strong-field field equation
Full field equation / gravity class	deferred	GR-II (Lovelock + mode count)
Metric is khronometric (Lorentz status)	I-from-GR-II	stated, not derived here; this paper works in the GR-coincident weak-field regime

All load-bearing steps are P, D, I, deferred, or labeled regime. *The single new postulate is P-Commitment-Linear; the single simulation validates a mechanism on an inherited-limit profile.*

3. The Emergent Spatial Metric

3.1 Bandwidth as the spatial metric

In the four-band bandwidth structure (P04), an edge $(\mathbf{u}, \mathbf{v})$ carries a reciprocal bandwidth $\mathbf{b}_{\mathbf{uv}} = \mathbf{b}_{\mathbf{vu}}$ (P02). Bandwidth measures coupling capacity: high bandwidth = strong coupling = short metric distance. The emergent spatial metric is

$$g_{ij} \sim b_{ij}^{-1},$$

with edge metric-length $1 \sim \text{sqrt}g \sim \mathbf{b}^{-1/2}$. This is the **explicit** form of the metric that Paper_033 introduced as a postulate (P-AcousticMetric): there the metric was an unspecified Lorentzian background; here it is the inverse bandwidth field, an object built from a single certified primitive.

Three properties hold by construction, and they are the genuineness conditions a metric must satisfy:

- **Symmetric** — $\mathbf{b}_{\mathbf{uv}} = \mathbf{b}_{\mathbf{vu}}$ (P02 reciprocal edge record), so $\mathbf{g}$ is symmetric.
- **Local** — built from local adjacency/bandwidth (consistent with ED's no-nonlocal-influence).
- **Positive in the bulk, degenerate at horizons** — $\mathbf{b} > 0$ gives a positive-definite spatial metric; where $\mathbf{b} \rightarrow 0$ (a decoupling cut), $\mathbf{g} \rightarrow \text{inf}$ — the metric degenerates *exactly* at emergent horizons, the correct behavior, not a defect. This $\mathbf{b} \rightarrow 0$ locus is the same surface the ED horizon literature identifies as a decoupling/saturation boundary (the emergent-boundary A2 and finite-memory-horizon V5 results), so the metric degenerates precisely

where ED already places its horizons; the identification (including khronometric “universal horizons”) is developed in GR-II.

$g_{ij} \sim b^{-1}$ is Riemannian (positive-definite) — the **spatial** sector. The Lorentzian (temporal) structure is the content of §4.

3.2 Consistency with the Newtonian limit

Writing $g_{00} = -(1 + 2\Phi)$ in the weak field, the inherited Newtonian recovery (Paper_027) is $\nabla^2 \Phi = 4\pi G \rho$. Identifying the bandwidth deviation with the potential, $b \sim 1 + 2\Phi$, the Newtonian limit reads $\nabla^2 b \sim \rho$. **This identification is the standard weak-field gauge choice (isotropic gauge, §1.4); it is a consistent labeling of the Newtonian potential, not a smuggled GR structure — any gauge-equivalent choice yields the same Poisson equation $\nabla^2 \Phi = 4\pi G \rho$.** This is the one place Paper_033’s postulated metric is constrained, and the bandwidth metric agrees there by construction. The new physics is in the *spatial* part and the *lapse*, which Paper_033 left open.

4. The Temporal Lapse from the Commitment Rate

4.1 The front is the null cone

The substrate front — the propagating locus of new commitments — is the **maximal signal** of the substrate: nothing propagates faster than the finite-width bandwidth-limit speed ($V1$ / Paper_089). In the emergent metric, the maximal signal travels on the **null cone**. **In a Lorentzian metric the maximal signal speed *defines* the null cone, so identifying the substrate’s maximal signal (the front) with the null cone is not an additional assumption but the definition of the emergent causal structure.** So the front worldline satisfies $ds^2 = 0$. (That front propagation is specifically *geodesic* — the front follows the locally fastest channel, a discrete Fermat principle — is established for the null sector in the Phase-3 analysis and used in §6; here we need only that the front is null.)

4.2 The null condition forces $N^2 \sim b$

Assemble the static metric $ds^2 = -N^2 dt^2 + g_{ij} dx^i dx^j$, with dt the homogeneous substrate tick (P13) and $g_{ij} \sim b^{-1}$ (§3). The front advances Γ edges per tick, where $\Gamma = \Gamma_{\text{commit}} \sim b_{\text{int}}/\text{reserve}$ is the certified commitment rate — linear in bandwidth, $\Gamma \sim b$, by **P-Commitment-Linear** (§2). Substituting the front’s coordinate velocity $dx/dt = \Gamma \sim b$ into the null condition:

$$0 = -N^2 dt^2 + g_{xx} dx^2 = dt^2(-N^2 + b^{-1}\Gamma^2) = dt^2(-N^2 + b^{-1}b^2) \implies \boxed{N^2 \sim b}.$$

The lapse is **forced** — not posited — by the commitment-rate law plus the null identification. The general case $\Gamma \sim b^\alpha$ gives $N^2 \sim b^{2\alpha-1}$, so the result is the single statement that the Einstein branch corresponds to **linear** commitment rate (§2): the physical reading of “commitment rate rises with available bandwidth” selects it; the conformal/Nordström branch would require the rate to *fall* with bandwidth.

Dimensional check. N is dimensionless (a lapse / redshift factor); b enters as the dimensionless ratio to its asymptotic value. ✓

4.3 Why the lapse matters

The lapse N is not a bookkeeping factor — it carries the relativistic physics, and all three classical tests flow from the single derived relation $N^2 \sim b$. (i) It *is* gravitational time dilation: clocks tick at rate $N \sim b^{1/2}$, which is the redshift (§5.4). (ii) It controls null propagation: the optical metric that bends light is $g_{ij}/(-g_{00}) = g_{ij}/N^2$ (§6.1), so the lapse enters the deflection directly. (iii) It is the *entire* difference between Newtonian/scalar and Einstein gravity — a theory with the spatial metric alone gives half the bending; the lapse, fixed by the commitment rate to scale as $N^2 \sim b$ in step with $g_{rr} \sim b^{-1}$, is what doubles it (§6.3). One field b sets both the spatial coupling and the temporal update rate, hence both spatial curvature and the lapse — which is why the two sectors are locked together.

5. The Weak-Field Metric and Two Classical Tests

5.1 The Schwarzschild relation

With $g_{00} = -N^2 \sim -b$ (§4) and $g_{rr} \sim b^{-1}$ (§3):

$$g_{00} g_{rr} \sim (-b)(b^{-1}) = -1.$$

This is the **Schwarzschild relation** — exactly the relation between the time and radial components of the Schwarzschild metric ($g_{00} g_{rr} = -1$), and the signature of the Einstein branch. The conformal (Nordström) branch, $g_{00} \sim -g_{rr}$, is excluded: it would require $N^2 \sim b^{-1}$, the non-linear commitment rate **P-Commitment-Linear** forbids.

5.2 The vacuum profile

The inherited Newtonian limit (§3.2) $\nabla^2 b \sim \rho$ gives, in vacuum ($\rho = 0$), $\nabla^2 b = 0$, whose spherically-symmetric solution is

$$b(r) = 1 - \frac{r_s}{r}, \quad r_s \propto M.$$

The $1/r$ profile is the standard Newtonian potential; r_s is the (value-inherited) gravitational radius. This profile is the Newtonian-order input; the full nonlinear determination is GR-II.

5.3 The weak-field Schwarzschild metric

Combining the relation (§5.1) and the profile (§5.2):

$$g_{00} = -\left(1 - \frac{r_s}{r}\right), \quad g_{rr} = \left(1 - \frac{r_s}{r}\right)^{-1}.$$

This is the **weak-field Schwarzschild metric** — the metric of General Relativity in the weak field. It is no longer postulated (as in Paper_033) but assembled from the bandwidth metric, the commitment-rate lapse, and the inherited Newtonian profile.

5.4 Gravitational redshift and perihelion precession

Two classical tests follow immediately:

- **Gravitational redshift (free corollary).** Clocks run at rate $N \sim b^{\{1/2\}}$. Near a source the bandwidth is depleted ($b < 1$), so $N < 1$: clocks run slow and light climbing out is redshifted, with the standard $\Delta\nu/\nu \approx \Phi$. Correct sign and law, from the same derived lapse.
- **Perihelion precession (test particle).** Timelike geodesics of the derived metric (§5.3) precess by the standard GR amount $\Delta\varpi = 6\pi GM/(c^2 a(1-e^2))$ per orbit. This follows by the textbook geometric calculation in the Schwarzschild metric. **The identification of ED's massive-matter worldlines with these timelike geodesics is *assumed* here and is tested in GR-II** (where the geodesic identity is extended from the null front to the matter sector via the stress tensor). This paper derives the precession only as a property of the *metric* — established here for null fronts (§4) — not yet as a property of ED's massive-matter dynamics.

The third and sharpest test — light bending — is §6.

6. The Factor of Two

6.1 The optical index

Light deflection in a static metric is governed by the **optical metric** $g^{\{opt\}}_{\{ij\}} = g_{\{ij\}}/(-g_{\{00\}})$, whose index is

$$n_{opt} = \frac{\sqrt{g_{rr}}}{N} \sim \frac{b^{-1/2}}{b^{1/2}} = b^{-1}.$$

The optical index is b^{-1} — the **square** of the spatial-only index $b^{\{-1/2\}}$. This is the crux: the spatial metric and the temporal lapse, *both built from b*, contribute equally to bending.

6.2 The deflection doubles — derivation and simulation

Weak-field deflection is $\alpha \sim \int \text{grad}_{\perp} \ln n$. Since $\ln(b^{-1}) = 2\ln(b^{-1/2})$, the deflection from the full optical index is **exactly twice** the deflection from the spatial part alone — the Einstein factor of two. Quantitatively, for $b = 1 - r_s/r$, $\alpha = 2 r_s/\xi$ at impact parameter ξ (versus the Newtonian r_s/ξ).

A self-contained eikonal ray-tracer (front = ray in index field, $dT/ds = \text{grad}_{\perp} \ln n$) confirms it across three index classes:

index class	C = $\alpha \cdot \xi$ (sim)	prediction
spatial-only / Newtonian $n = b^{-1/2}$	-1.07	$-r_s$
Einstein / optical $n = b^{-1}$	-2.24	$-2 r_s$
conformal / Nordström $n = 1$	0.00	0

The Einstein/Newtonian ratio is **2.09** (the $\sim 4\%$ excess is finite- r_s weak-field curvature, not a physical deviation); the conformal control is exactly zero; the deflection is $\sim r_s/\xi$ and $\sim M$, the gravitational-lensing signature. **The simulation validates the propagation mechanism on the inherited-limit profile (§5.2); the profile itself is not re-derived here (preamble 7).**

Reproducibility. The ray-tracer integrates the eikonal equation $dT/ds = (1/n)[\text{grad } n \cdot T]$ (equivalently $dT/ds = \text{grad}_{\perp} \ln n$) by explicit first-order (Euler) steps in arc length s , renormalizing the unit tangent T after each step. Parameters: step $ds = 0.02$; source strength $r_s = 1$ with softened profile $b(r) = 1 - r_s/r$ (core regulator 10^{-3}); index $n(r) = b(r)^p$ with $p \in \{-1/2, -1, 0\}$ for the three classes; rays launched in the asymptotically flat region at $x = -400$ (in units of r_s) with impact parameters $\xi \in \{10, 15, 20, 30, 40, 60, 80\}$ and integrated to $x = +400$, where $b \rightarrow 1$; the deflection is the asymptotic tangent angle. There is no spatial grid and no reflecting/periodic boundary — propagation is free in the imposed static index field. Scripts: `gr_lensing_test.py`, `gr_einstein_factor.py`.

6.3 Why the factor is two and not one

Newtonian or pure-scalar gravity curves *time* (a g_{00} potential) but leaves space flat, giving half the deflection. Pure conformal (Nordström) gravity curves space and time *equally and oppositely*, so the optical effects cancel and light does not bend at all. Einstein gravity curves space as much as time *in the same sense*, doubling the deflection. ED lands on the Einstein case because **one field, b , sets both sectors** ($g_{rr} \sim b^{-1}$, $N^2 \sim b$), with the commitment-rate lapse fixing the sign that makes them reinforce rather than cancel. The factor of two is the fingerprint of that single-field origin.

Historical note. The factor of two is the discipline’s classic discriminator. Soldner (1801), and Einstein’s first attempt (1911) using only the time potential g_{00} , gave the Newtonian value $2GM/c^2\xi$; Einstein’s 1915 result, adding the *equal spatial curvature*, doubled it to $4GM/c^2\xi$, confirmed by Eddington in 1919. Relativistic-MOND covariantizations had to **add a vector field** (e.g. TeVeS) precisely to install the spatial curvature and recover the factor of two. ED reaches it from a single field because b sets both sectors at once — no added vector required.

7. Position Relative to the Published Acoustic-Metric Arc

This paper sharpens, and does not contradict, Paper_033. The relationship is precise:

- **Paper_033 postulates the metric.** Its acoustic metric is introduced by P-AcousticMetric (labeled a postulate in its own audit), with unspecified form. **The key fact that dissolves any “two metrics” worry: Paper_033 never computes the**

spatial curvature or the light-bending coefficient at all — its only metric-level constraint is the Newtonian limit, so there is no published value for this paper to contradict, only an unspecified slot for it to fill.

- **This paper derives the metric.** $g \sim b^{-1}$ is explicit, agrees with Paper_033 at the Newtonian limit, and supplies what Paper_033 left open: the spatial part (Einstein factor of two) and the lapse ($N^2 \sim b$). The bandwidth metric is the **explicit realization** of Paper_033’s postulated background, sharpening “unspecified Lorentzian background” into “Einstein-class at weak field.”
- **The Lorentz status.** Because the lapse comes from the commitment-rate law, the metric carries a preferred-foliation (khronometric) structure — Einstein-class at weak field, but not pure GR. This is stated here and derived in GR-II. It revises Paper_033’s implicit Lorentz-covariance into a khronometric structure that *coincides with GR in the regime this paper treats*.

Two reconciliation items remain open and are declared, not hidden:

1. **Substrate-route identification.** This paper builds the metric from P04 bandwidth; Paper_033 attributes the (postulated) metric to P02/P03/P06 strain/flow. Whether b is fixed by the strain/flow content — so the two substrate routes yield the same metric — is unproven. (Paper_033 never carried out the strain→metric construction either, so this is “two routes agreeing at Newtonian order,” not two incompatible explicit metrics.)
2. **The MOND sector.** Paper_033’s relativistic-MOND content ($a_0 = cH_0/2\pi$, BTFR) lives in a scalar field with a MOND interpolation. The companion khronometric picture (GR-II) carries a preferred-foliation scalar (the khronon); whether that scalar reproduces a_0 and BTFR — unifying the Einstein-at-solar-scale and MOND-at-galactic-scale regimes — is open and is the natural next target.

8. The Wedge — Empirical Content

At weak field the derived metric **coincides with General Relativity**, so this paper makes no wedge claim *against* GR at solar-system scale: light bending (factor of two), redshift, and precession match GR by construction of the weak-field Schwarzschild metric. The empirical content of this paper is therefore **internal and structural**:

1. **ED recovers the factor of two** — the first genuinely relativistic gravitational prediction — from a single substrate field, not by adding a vector (as relativistic-MOND covariantizations such as TeVeS must). This is a non-trivial consistency that a sub-Einstein substrate theory would fail.
2. **The mechanism is sign-and-coefficient-definite**, tied to P-Commitment-Linear: a substrate-level demonstration that the commitment rate is *not* linear in bandwidth would push ED off the Einstein branch toward Nordström (no bending) — a sharp internal falsifier (§9).

The *external* wedge against GR — preferred-frame effects, the scalar gravitational-wave sector — is khronometric and lives in GR-II / phenomenology, where ED and pure GR diverge.

9. Falsification Criteria

9.1 Commitment rate not linear in bandwidth

Falsifier sentence: *A substrate-level demonstration that the commitment rate Γ_{commit} is not linear in the metric-relevant bandwidth ($\alpha \neq 1$) — e.g. that the commitment-reserve band co-scales with the internal band, giving $\alpha = 0$ — would falsify P-Commitment-Linear, hence the lapse $N^2 \sim b$, hence the Schwarzschild relation, and would push ED's weak-field gravity off the Einstein branch (toward conformal/Nordström, no light bending).*

9.2 Spatial metric not b^{-1} (wrong light-bending coefficient)

Falsifier sentence: *A substrate-level emergent metric whose spatial part is not $g_{\{ij\}} \sim b^{-1}$ — e.g. a flat spatial part ($g_{\{ij\}} \sim \delta_{\{ij\}}$) — would give the Newtonian (half) light-bending coefficient rather than the Einstein (factor-of-two) value, falsifying §6.*

9.3 Front not null / not the cone

Falsifier sentence: *A substrate-level analysis showing the front (maximal signal) is not identified with the metric null cone would invalidate the §4.2 lapse derivation.*

9.4 Bandwidth metric disagrees with the acoustic metric beyond Newtonian order

Falsifier sentence: *A demonstration that the P04 bandwidth metric and the P02/P03/P06 strain/flow content yield different metrics beyond the Newtonian limit (where both are pinned) would falsify the §7 identification of $g \sim b^{-1}$ as the explicit realization of the Paper_033 acoustic background.*

9.5 Light bending not the factor of two

Falsifier sentence: *Empirical observation of solar-system light bending inconsistent with the GR factor of two (beyond the established $4GM/c^2 x_i$) would falsify the derived weak-field metric — though this is also a falsifier of GR itself, with which the derived metric coincides at weak field.*

10. Position Statement

The **weak-field Einstein metric** is a downstream structural derivation in the ED Generative Primitives System. Given the postulated primitives + the inherited Newtonian base (Paper_027) + the explicit bandwidth metric $g \sim b^{-1}$ + the postulate that the commitment rate is linear in bandwidth (P-Commitment-Linear), the weak-field metric follows:

- spatial metric $g_{\{ij\}} \sim b^{-1}$ (§3);
- lapse $N^2 \sim b$ from the commitment-rate law and the null condition (§4);
- Schwarzschild relation $g_{\{00\}} g_{\{rr\}} \sim -1$ (§5.1) + inherited Newtonian profile (§5.2) → weak-field Schwarzschild metric (§5.3);
- factor-of-two light bending (§6), gravitational redshift (§5.4), perihelion precession (§5.4).

What this paper claims. Given the inherited Newtonian base and P-Commitment-Linear, the ED weak-field metric is the Schwarzschild metric, and ED reproduces the three classical weak-field tests — including the factor of two — from a single substrate field. It supplies the explicit metric that Paper_033 postulated.

What this paper does not claim. The 13 primitives are not derived; G and l_P are inherited; P-Commitment-Linear is postulated, not derived; the source profile is the inherited Newtonian limit, not a strong-field field-equation solution; the full field equation and the gravitational class (khronometric) are deferred to GR-II; and ED gravity is **not** pure General Relativity — it is khronometric, coinciding with GR in the weak-field regime treated here. The bandwidth $\leftrightarrow$ strain/flow and khronon $\leftrightarrow$ MOND identifications remain open (§7).

Series context. Paper GR-I of the post-pivot curvature-emergence line. The companion **GR-II** derives the field-equation form (Lovelock) and the gravitational class (mode count $\rightarrow$ khronometric), and addresses Lorentz safety.

Appendix: Cross-References and Glossary

Cross-references

- **Position paper:** Paper_087.
- **Paper_027 / 027.5:** Newton recovery; $G = c^3 l_P^2 / \hbar$; $l_{ED} = l_P$.
- **Paper_033:** acoustic-metric scalar-tensor covariantization (postulated metric; sharpened here).
- **Paper_073:** DCGT continuum-limit bridge.
- **Paper_089:** V1 finite-width retarded kernel (cone / bandwidth-limit speed).
- **GR-II (companion):** field-equation form + gravitational class (khronometric) + Lorentz safety.

Glossary

- **Bandwidth metric $g_{ij} \sim b^{-1}$.** The emergent spatial metric, inverse of the P04 edge bandwidth.
- **Lapse N .** The $\sqrt{-g_{00}}$ factor; here derived as $N^2 \sim b$.
- **Commitment rate $\Gamma_{\text{commit}} \sim b_{\text{int}}/\text{reserve}$.** The certified rate at which a front commits; taken linear in b (P-Commitment-Linear).
- **Schwarzschild relation $g_{00} g_{rr} \sim -1$.** The time–radial metric relation characteristic of the Einstein (not conformal) branch.
- **Optical index $n_{\text{opt}} \sim b^{-1}$.** The light-propagation index; the square of the spatial index, hence the factor of two.
- **Factor of two.** The Einstein light-bending coefficient ($4GM/c^2 \xi$), twice the Newtonian value; arises because b sets both spatial and temporal sectors.
- **Null front.** The substrate front — the propagating locus of new commitments — identified with the null cone of the emergent metric because it is the substrate’s maximal signal (§4.1).
- **Khronometric.** Einstein’s tensor sector plus a preferred-foliation scalar; ED’s gravitational class (GR-II), coinciding with GR at weak field.

Reader map and open work

Where to look next. - *The field equation and gravitational class (khronometric):* GR-II. - *Lorentz safety, gravitational-wave speed, preferred-frame phenomenology:* GR-II. - *The MOND sector ($\mathbf{a}_0$, BTFR) and its relation to the khronon:* Paper_033 + GR-II. - *The substrate-route identification ($\mathbf{b} \leftrightarrow \text{strain/flow}$):* the reconciliation memo.

Open work (declared, not hidden): (1) derive $\mathbf{b}$ from the P02/P03/P06 strain/flow content, closing the substrate-route gap (§7); (2) fix the reserve dynamics that pin $\alpha = 1$ in P-Commitment-Linear (§2); (3) the strong-field / nonlinear regime and the timelike-geodesic identity (GR-II); (4) the khronon $\leftrightarrow$ MOND unification (§7).

End of Paper GR-I.

Post-pivot curvature-emergence line. Weak-field Einstein metric from the bandwidth metric + the commitment-rate lapse. Headline: $N^2 \sim \mathbf{b} \implies g_{00} \ g_{rr} \sim -1$ (Schwarzschild relation) and the factor-of-two light bending, from a single substrate field; the explicit realization of Paper_033's postulated acoustic metric. Field equation and gravitational class: GR-II.
